Game-Theoretic Economics of Compounding Capability

Executed production. Strategic markets.
Financeable improvement.

A tested production asset.
Conditional value from deployment.
Generated funds without a qualified successor.

Four fresh maintenance decisions. Strong conventional parity. A bounded continuation exposes both a viable modeled region and its failures. Historical research repayment and financing of a second tested improvement remain unestablished.

A reproducible research experiment with a bilingual interactive companion.

Prepared for the AGI ALPHA research programme.
AI-assisted engineering, analysis and manuscript preparation disclosed.
26 October 2026 · Evidence edition 1.0

No customer transaction, token distribution or deployed-contract change.

Abstract

Useful recurring work can finance capability improvement only when buyers choose it, delivery creates collected surplus, and a tested asset repays its complete cost. We connect executed AGI ALPHA production to an externally anchored, cash-constrained procurement simulation that includes heterogeneous buyers, human providers, conventional software, competing AI and deferral. Four prospectively frozen joint dependency changes produce twelve complete scoped assessments; the retained producer and a strong conventional builder both automate finalization and tie on accepted quality. Active human minutes and all-in engineering/authoring money remain unidentified.

The primary 87-condition experiment produces no profitable enterprise or adoption. A preserved 206-condition exploratory extension produces only six adoptions under seed-inclusive funding and no positive-mean enterprise condition. Existing histories then expose a poor pricing heuristic, motivating a publicly frozen final diagnostic of all five previously declared target-price policies. Across its 160 conditions, four have positive mean prospective-operator profit, all occurring at zero integration cost, the higher assumed work arrival and seed-inclusive adoption excluding sunk research. In the preselected \$20 target, logit condition, mean B profit is \$183.28 and paired B-minus-A gain is \$184.97 (conditional 95% Monte Carlo interval \$140.80–\$229.13). Including the declared historical research bill changes mean B profit to $\$ - 178.24$ and the incremental effect to $\$ - 176.55$. No configuration has positive mean full-history profit or investment effect. No initial adoption meets the original strict earned-funds policy. B/C remain exact modeled ties.

A separately registered 128-condition continuation uses 24 fresh seeds without changing the horizon, capital or core. Its reference mean prospective profit is \$151.70 and paired gain \$173.67; three of 24 paths lose money. Nonzero integration, lower recurrence, maintenance, collection delays, competing strategies and another buyer rule map the limits and expose non-monotone responses to payment timing and competitor policies. No full-history condition has positive mean profit or paired gain. These new monetary results precede an explicitly unpriced second-asset discovery cost.

Some enterprises generate resources during the year. A preselected path has \$351 of operating-generated funds after all declared prospective costs, with its reserve protected, while full-history profit remains $\$ - 10.52$. No second candidate passes the bounded qualification gate, so none is constructed or purchased. The complete 9,552 paired histories preserve failures, bills, invoices, collections, assets and cash decisions. The supported result is conditional deployment value under seed-inclusive initial funding and a possible supply of generated funds. Full-cost repayment, earned financing of a subsequent tested asset, actual market receipts, method superiority and self-acceleration remain unestablished.

Evidence vocabulary. **EXECUTED** denotes actual local production and resource observations. **SIMULATED** denotes outcomes inside the declared procurement model. **UNIDENTIFIED** denotes costs or market relationships that current evidence does not identify. A simulated invoice is not a sale observed in the world; a finite component pass is not field reliability.

Contribution and reading guide

This study connects a real source-bound capability to a market that is allowed to refuse it. The contribution is an inspectable link between scoped production, strategic procurement, finite cash and an exact investment identity. It also exposes a policy failure that would otherwise be mistaken for a commercial failure. The simulator uses the existing canonical economic ledger, rather than

creating a second accounting authority. The useful outputs and all failed economic cases remain reproducible.

Sections 1–3 establish the offering and actual asset. Sections 4–6 define the market, calibration and cash constraints. Sections 7–9 report the original frozen experiments, sensitivity and causal limits. The bounded succession continuation then separates deployment, historical return and generated resources. The appendices give custody, protocols, resource boundaries and replay commands. The companion includes the complete histories; the paper presents the decision-relevant results.

1 The commercial mechanism and three distinct questions

A capability is commercially useful only if it helps deliver something a buyer values more than the price, remaining work, uncertainty and practical alternatives. Lower supplier cost creates room for a better offer. It does not make that offer desirable. Even a desirable offer can fail to fund improvement when sales are sparse, invoices arrive late, reserves are binding or the engineering bill exceeds incremental benefit.

The proposed loop therefore contains separate gates:

$$\text{useful changed work} \longrightarrow \text{chosen and accepted delivery} \longrightarrow \text{collected surplus} \longrightarrow \text{affordable tested asset.}$$

The new asset must subsequently improve fresh useful work enough to repay its complete cost. Any next construction step must meet the same requirements. Scheduling more runs, repeating an unchanged input, accruing unpaid invoices or increasing a bank balance is insufficient.

We answer three questions separately. First, can the scoped offering attract buyers relative to competent human work, conventional software, competing AI and deferral? Second, does adopting the actual retained producer increase terminal enterprise value after its complete declared costs? Third, does the AGI ALPHA improvement process outperform an equally resourced conventional builder? The third answer can be a tie even when the first two are positive.

Within the investment question, the continuation distinguishes three economic decisions: prospective use of an already-built asset; recovery of its complete historical discovery, construction, verification, integration, failures and upkeep; and later operating resources financing another qualified improvement. A sunk expense remains in full return but is not charged again as new cash at every prospective decision. Seed funding is legitimate and is tracked separately from subsequent operating generation.

Let Π_A, Π_B, Π_C be terminal net enterprise economic outcomes under common exogenous scenario draws. The investment estimand is $\Delta_{BA} = \Pi_B - \Pi_A$; the builder comparison is $\Delta_{BC} = \Pi_B - \Pi_C$. A profitable B does not by itself establish a positive Δ_{BA}. Direct avoided labor expense is another quantity: demand, prices, downtime and competition can consume its apparent saving. These distinctions were written into the claim criteria before the primary market outcomes.

2 A useful recurring offering, bounded before scale

2.1 Buyer, deliverable and acceptance contract

The concrete buyer role is the maintainer of AGI ALPHA's native Python consumer. The decision is whether a changed dependency combination preserves the declared request-boundary and strict Mission/Review/Control input behaviors, and what evidence should enter wider qualification. The complete deliverable contains exact source and wheel identities, locked environments, before/after behavioral observations, execution receipts, independent verifier output, a scoped decision, a proposed component-lock patch, bilingual next actions and a replay path.

This can replace gathering and reconciling dependency evidence, running bounded checks, establishing provenance, assembling a reviewable decision and preparing its component patch. It does not replace the maintainer's release authority, full application testing, security review or production deployment. The accepted result is a complete, internally consistent assessment: verified preservation, a supported regression/hold decision or a clearly delimited outcome. Missing or conflicting evidence is incomplete work; it does not qualify for acceptance revenue.

The native consumer and its requirements are real project obligations. Public maintenance practice also supports recurrence: GOV.UK documents dependency-update management, grouping,

automation and qualified human review [9]. A documented Starlette/HTTPX incompatibility illustrates an actual upgrade-versus-pin decision, not a new customer in this study [12]. Another mission is warranted when the consumer contract, relevant source or complete dependency tuple changes. Repeating an unchanged tuple, evaluating another arm or counting its 61 assertions creates no new job. Neither release frequency nor this small research sequence identifies a buyer's purchase rate.

2.2 Discovery choices and rejected work

We bounded discovery around a task that requires a consumer-specific decision, not an API diff alone. Dependabot creates update pull requests; Renovate offers a free hosted community tier; Griffe checks public Python API compatibility [5, 4, 6]. A bare version list is commercially weak against these alternatives. The proposed value lies in a complete source-bound decision packet, with remaining review and integration costs kept explicit.

We did not select a cross-mission baseline cache as a second investment. In the preserved execution, baseline and target probes run concurrently and share a real 15-second timeout. Removing one probe would not halve turnaround; at best it would avoid a small amount of CPU work. Construction, custody and upkeep could outweigh that benefit. A new importer was also rejected because the existing product owner already maintained that route. These decisions prevent a large financial model from financing an insignificant optimization or a duplicate runtime.

3 Executed production and the exact retained asset

3.1 Prior work, preservation and new evidence

The existing Useful Work v2 study contains six historical dependency transitions, evaluated by three arms. It reports accepted scoped assessments in all arms, six explicit AI researcher finalizations in A and none in B/C [13]. We preserve that campaign separately. Earlier research found that a conventional method could exceed a custom candidate; its failed candidate is not relabeled as a financeable successor [14]. The existing commercial edition remains an illustrative predecessor, not empirical evidence for a $99 price or assumed customer attention savings [15].

For this study we froze four new combined tuples before observing their outcomes. They combine previously seen package bodies in previously unexecuted joint inputs. The baseline is Starlette 1.7.0, Pydantic 2.13.5 and pydantic-core 2.46.5. FastAPI 0.141.1 and the original consumer remain fixed. The target matrix is:

Mission	Starlette	Pydantic	pydantic-core
joint-1	1.8.0	2.14.0	2.50.0
joint-2	1.9.0	2.14.0	2.50.0
joint-3	1.8.0	2.14.1	2.50.1
joint-4	1.9.0	2.14.1	2.50.1

The full Cartesian selection, acceptance contract, implementations, sequence and input identities were frozen in 144 files. The public prospective notice is preserved in issue #4850 [16]. Each arm receives one execution per mission, balanced across order, with no automatic retry or replacement input. The research-proposed grouped options are four new maintenance questions, not four paid orders or independent defect families.

3.2 A structural representation change with honest attribution

A uses the strong existing execution and packaging helpers, with an explicit researcher disposition. B uses `src/package_component.py`; C uses `src/conventional_package.py`. B creates the decision, source bindings, receipt checks, component-lock patch and bilingual evidence inventory together. The change is structural: evidence and the delivered decision are built as a mutually checked representation, instead of assembling an externally supplied disposition after execution.

The creator–critic process found provenance and negative-result weaknesses. B explicitly adopted C's stronger receipt checker. This is legitimate method reuse and AI-assisted research engineering. It is not autonomous invention or demonstrated algorithmic superiority. The financed asset in the simulation is exactly this source-pinned producer, not a hypothetical later system.

Both B and C use the unchanged local research adapter and the existing `createWorkbench([adapter])` route. The existing job graph covers constitution, evidence, formation, challenge, verification, admission and renewal. Mission, source and release digests bind its delivered artifacts. Eight new B/C native packs retain `HOLD`, empty authority and disconnected settlement. An unfunded review-capacity field is not observed labor or permission. No held Fleet/Harness execution profile, service, contract or operator was activated.

3.3 Measured outcomes and resource limits

All twelve assessments met the unchanged finite contract: 61 requirements before and 61 after each tuple, with complete records and scoped preservation. A required four explicit AI research-agent finalizations; B and C required none. These are action counts, not measured competent-human minutes. No construction or delivery bill can be inferred from mechanical elapsed time.

Table 1: Actual fresh production. Means are descriptive across four related tuples. All-in money and active human attention remain unknown.

Arm	Accepted	Explicit finalizations	Wall/job (s)	CPU/job (s)
A: ordinary helpers	4/4	4	16.647	2.288
B: retained producer	4/4	0	16.746	2.473
C: conventional producer	4/4	0	16.799	2.539

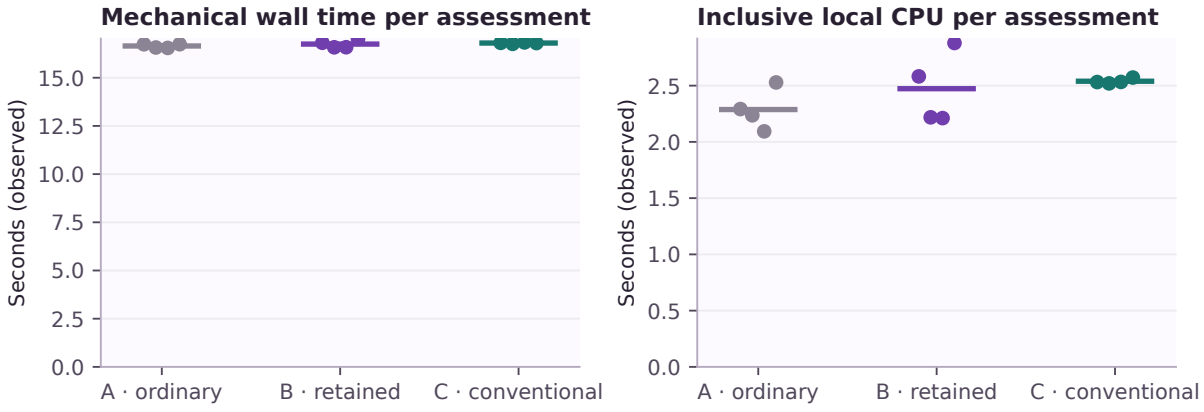

Figure 1: Executed evidence, without an assumed speed premium. Each point is an actual arm/tuple observation. The retained producer removes an explicit finalization action, while the mechanical runtimes show no established economic speed advantage.

The exact campaign records setup CPU of 19.894 seconds, inclusive delivery CPU of 29.198 seconds and packet-packaging CPU of 0.056 seconds. These phase totals must not be added to nested per-job diagnostics a second time. They exclude unmeasured authoring, discovery and human work. The source freeze remains unchanged; 448 packet payload hashes were checked. A clean relocated replay rebuilt two environments from offline wheels and reproduced the same joint-1 semantic result through the unchanged B Workbench. It is verification of the original mission, not an additional customer job.

4 The strategic market, explicitly

4.1 Players, information, actions and timing

The model is a behavioral agent-based repeated procurement game with strategic posted-price responses. It is not a solved equilibrium. There is no Nash, convergence, optimal-policy or market-clearing claim.

There are twelve heterogeneous project buyers, one studied enterprise, a competent human provider, a competing AI service and each buyer's conventional DIY option. Deferral is always available. The three enterprise arms are separate common-draw counterfactual worlds, not three firms bidding simultaneously against each other. Each starts with equal resources, information and customer draws. B and C can construct or adopt the same class of reusable asset; neither is forced to reinvent it.

Each of 52 weeks first resolves due collections and bills, then accrues overhead and upkeep, evaluates investment, posts prices and processes fresh supported opportunities in keyed random order. Delivery and attention capacities bind. Accepted work generates invoices; rejected work retains its cost without acceptance revenue. Delayed feedback changes trust and can cause churn. After week 52 a drain interval resolves contracted collections/refunds without generating new work.

Buyers know their own task value, effort cost, budget, available offers and past outcomes. They do not observe true future quality. Providers see past sales and public prices, not future draws or private buyer values. Available actions include choosing or deferring work, switching, excluding a disappointing provider temporarily, adjusting a posted price, adopting an asset, maintaining it, retaining reserves and stopping after insolvency. Every firm has finite cash and capacity. The simulation's hypothetical competitor automation is an explicitly assumed response, not technology constructed by this study.

4.2 Buyer payoff and feasible choices

For buyer i, provider j and week t, modeled expected surplus is

$$U_{ijt} = \hat{q}_{ijt}V_i - p_{jt} - w_i e_{ijt} - (1 - \hat{q}_{ijt})L_i - d_{ijt} - s_{ijt}. \tag{1}$$

Here V_i is expected useful task value, p the posted price, we remaining customer effort, L consequence of an error, d delay cost and s switching/integration cost. The value prior is an assumed multiple of wage-equivalent task effort, not revealed willingness to pay. Buyer-specific trust uses bounded Beta-style counts and delayed outcome feedback; the finite component passes are not inserted as unbiased field-quality estimates.

An offer is unavailable when the buyer budget, provider capacity, financeability or temporary exclusion prevents delivery. Offers weakly worse on quality, price, effort, delay and switching cost, and strictly worse on at least one, are removed. Under deterministic choice the highest strictly positive utility wins. An alternative logit rule samples only from positive-utility, nondominated

feasible offers plus deferral at utility zero. Thus a random taste shock cannot make a strictly dominated offer win. This is a deliberate behavioral restriction, not a fitted consumer-choice law.

A finite procurement allocation is committed on accepted invoices. Refunds/defaults do not restore it, a conservative simplification. Each buyer has at most one new changed-input opportunity per week; unsupported opportunities cannot generate an enterprise job. The assumed scope fraction and arrival process do not extrapolate the experiment to the digital-work market.

4.3 Competition and price responses

The ordinary enterprise explores the declared \$5, \$10, \$20, \$40 and \$80 targets using past conversion and a margin-weighted exploration score. This is a finite-horizon heuristic, not competent optimization by definition. Fixed-target and cost-pass-through policies already exist in the frozen core. A fixed target posts at least current unit cost plus \$1; a low target can therefore produce different realized prices before and after adoption.

The human provider can compress markup toward cost after poor sales. The AI competitor can respond to sales or undercut within a floor; an adequately funded competitor can purchase its assumed cost reduction after a declared date. Its cash, obligations, sales and automation action are recorded. Alternative fixed and adverse strategies are tested. No provider receives unlimited free improvements, and the conventional DIY option retains its customer's effort cost.

5 Calibration: attributable anchors and unidentified quantities

Table 2: External evidence constrains the model without identifying the exact offering's price. Sources were checked on 26 October 2026.

Evidence	Attributable observation	Permitted interpretation and limitation
BLS wages	May 2025 median developer \$135,980/year; QA \$104,300/year [1]	Labor opportunity-cost anchor. Dividing by assumed 2,080 annual hours gives \$65.375 and \$50.144/hour; not a bill rate or task duration.
BLS compensation	June 2026 private wages \$32.82/hour; total compensation \$46.89/hour [2]	Benefits-loading sensitivity across occupations, not measured software-specific construction cost.
Historical contracts	Upwork Python typical \$20–\$40/hour; median \$30 [3]	A cheaper competent-human alternative. Worldwide historical platform summary, not a quote for this packet.
Conventional tools	Renovate community hosted tier has zero license price; Dependabot creates update PRs [4, 5]	A strong incumbent with remaining setup, test and review effort. Zero license price is not zero total cost.
Advertised AI plans	Copilot Pro \$10/month; CodeRabbit Essentials \$30/month or \$24 annual-billed equivalent [7, 8]	Alternative budget scale. Subscription prices are not complete-deliverable transactions or unlimited task capacity.
Maintenance practice	GOV.UK documents recurring dependency obligations and qualified automation [9]	Observed need for maintenance. Does not establish this study's buyer arrival rate or willingness to pay.
Adoption attitudes	Stack Overflow 2026 reports heterogeneous trust in AI output [10]	Motivates competing trust models. Survey responses are not purchase probabilities or population weights.

The full source manifest has fifteen primary-source entries, each with what it supports and what it does not. Advertised offers, historical transactions, public budgets, attitudes and actual study purchases are distinct evidence classes. This study observes no completed purchase of its exact offering. A primary empirical study of Dependabot compatibility scores motivates consumer-specific evidence but cannot calibrate present commercial demand [11].

The reference scenario uses a $65.38 provider-hour anchor, $30 human-provider-hour anchor and heterogeneous buyer-hour anchors of $30, $50.14 and $65.38. Transporting wages to this task and combining these groups are assumptions. Task durations of 30/60/90 minutes, remaining review of eight minutes, a 1.25 usefulness multiplier, error loss, trust priors, reliability and payment behavior are unidentified. No implicit conversion of an AI researcher action into ten human minutes is made: zero, two, ten and thirty avoided minutes are separately declared scenarios.

Default initial capital is $\$1,000$, reserve $200, setup $50 and weekly overhead $2. The market-size convention is twelve projects, not an estimated total addressable market. The default $0.25 compute/tool allowance is an assumption, not an invoice. Full historical engineering cost is also unidentified. The illustrative four-hour case plus a $100 authoring allowance gives $361.52; it is neither a measured total nor an upper bound. Failure/discovery shares allocate that total rather than adding a second copy.

The parameter manifest records every default and classification. Primary scenarios, later exploration and stress inputs remain separate. Very weakly identified quantities may lie outside every displayed range; apparent robustness inside the grid is not empirical identification.

6 Exact-asset finance and accounting

6.1 Cash, accrued expense and economic outcome

Every event is explicitly typed as simulated. For enterprise f,

$$C_{t+1} = C_t + \text{Collections}_t - \text{CashPayments}_t, \qquad C_t \geq 0. \tag{2}$$

Bills accrue once and remain obligations until paid. A due bill that cannot be paid marks insolvency and stops new delivery. Revenue is not earned by rejected work; accepted but uncollected invoices remain separate from collected money. Defaults, refunds and delivery failure costs are retained. Economic profit is recognized invoices net of defaults less every accrued cost, including refunds and unpaid obligations. After the complete collection drain, recognized net invoices equal gross collections. Seed capital is never revenue.

The unchanged `alpha-shadow-ledger/v1` arithmetic supplies the economic and liquidity projections. Its native observed-collection category requires observed evidence. Therefore observed collections remain exactly zero, while simulated collections enter only an explicitly assumed-price projection with a `SIMULATED` wrapper. Refund adjustments are explicit, and paid costs are not added again to the same accrued expense.

6.2 Affordability and investment alternatives

An adoption is eligible only if the forecast benefit after upkeep, anticipated price pass-through and lost delivery during adoption exceeds its full prospective charge. The forecast uses only trailing eight-week accepted enterprise sales, remaining productive weeks and a declared discount. It cannot read future demand.

In addition, adoption cost must fit current cash net of obligations and reserves. The stricter earned-funding mode also caps it by accumulated collected operating surplus excluding seed

resources and uncollected invoices. Precisely, with accrued costs E_t, unpaid obligations O_t, reserve R and gross collections Y_t, its available amount is

$$F_t^{\text{earned}} = \min(C_t - O_t - R,\ Y_t - E_t - R).$$

This conservative policy also requires a reserve out of cumulative net earnings, even when initial capital supplies liquidity. It is an eligibility rule, not an additional cost or a theorem that smaller profits cannot finance adoption. Reserve sensitivity is available in the interface but was not swept in the final diagnostic. Seed-funded adoption is separately labeled. Installation takes at least one week, or the ceiling of adoption hours divided by available engineering hours; successful installation pauses service and no asset use is permitted before availability. The frozen failure branch charges the full adoption cost but treats a failed integration as immediately detected, allowing ordinary delivery to resume without forced downtime. Planned activation metadata is not evidence of failed-installation downtime; prolonged failures are not bounded by that stress.

The model records reconstruction cost and selects the cheaper public-method adoption route. The enterprise can retain its incumbent, adopt that solution, maintain an adopted asset, preserve funds or stop. B and C have equal access to the existing method. The same exact source identity appears in the investment record and every later use.

Full-history and prospective accounting answer different questions. Full-history accrues the assumed historical research bill at opening, funded from initial finite capital or left as an insolvency obligation. Earnings cannot retroactively finance that past work. The separately labeled adoption-only view charges future installation, verification and upkeep while excluding sunk research. It cannot establish repayment of omitted history. An explicit retrospective-cost-allocation stress is retained but never called historical research affordability.

No second productive successor is supplied. The next-investment action remains retain reserves unless a distinct constructed, tested and worthwhile asset exists. This is a substantive limit on the claimed flywheel, not a missing bookkeeping entry.

7 Prospective primary experiment and preserved failures

The primary source, scenarios, seeds and claim criteria were frozen before execution and publicly recorded [17]. Eighty-seven configurations crossed avoided minutes, historical construction or adoption assumptions and two buyer rules, plus named stresses. Twenty-four independent seeds (1001–1024) yielded 2,088 paired worlds and 6,264 enterprise histories. Semantic random keys exclude arm names, so random-call order cannot create an artificial B/C advantage.

Primary result. No world adopted the capability and no enterprise trajectory had positive complete scenario profit. Under reference assumptions A loses \$154; B and C each lose \$515.52, including the declared \$361.52 historical charge. All three attract zero accepted enterprise sales in that reference condition.

This does not demonstrate financeable improvement under the specified primary policies and assumptions. It does not establish that every possible offering or competent pricing policy fails. B/C tie exactly because their modeled effects, costs and random draws are equal. The finite production observations justify avoiding an unsupported AGI ALPHA premium; they do not empirically identify equal total construction cost.

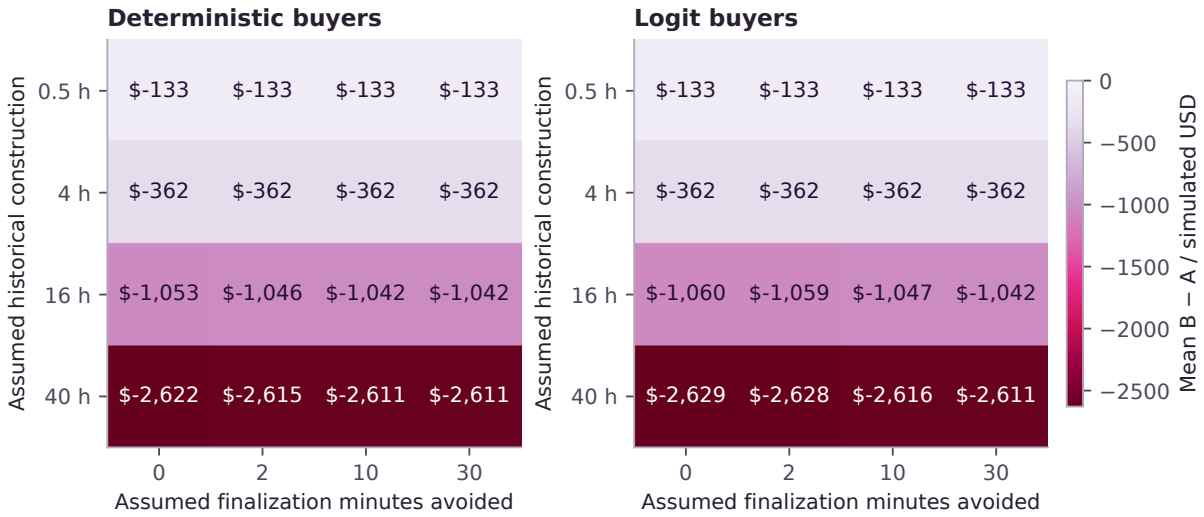

Figure 2: Primary full-history grid: mean B-minus-A economic outcome in simulated USD. Historical hours include the same declared authoring allowance. No cell adopts, so the investment comparison retains the opening historical charge without a later operating saving. Both buyer rules and all failures are preserved.

The primary stresses include no/low demand, cheap humans, cheap competing AI, price competition, slow collections, dissatisfaction, switching barriers, quality shock, high upkeep, failed integration, skeptical buyers, cash constraints and a free perfect conventional option. These are adverse tests, not alternative favorable calibrations selected for publication.

8 Exploration and pricing-policy diagnosis

8.1 Postprimary exploration with no replacement of the primary result

A second protocol was designed and publicly frozen after inspecting the primary null [19]. It is explicitly exploratory. The same frozen core evaluated integration costs of \$0/\$10/\$50, arrival probabilities .25/.5, avoided minutes 0/2/10/30, two buyer rules and four historical/prospective and earned/seed financing regimes. Fourteen adverse corners added the declared stresses to a low-friction condition. The 206 configurations used twelve new seeds (2001–2012), totaling 2,472 paired worlds.

Only six B worlds adopted, all under the seed-inclusive policy. Seventeen individual B worlds were profitable, all in adoption-only accounting, and no configuration had positive mean B profit. The sole configuration with positive mean B-minus-A difference produced \$18.49, with a conditional normal-approximation 95% Monte Carlo interval of [\$ − 15.17, \$52.16]. Its mean B profit was \$ − 103.83. This is not a robust profitable enterprise or financing from earned surplus. The grid fractions are not estimates of real-world customer probabilities.

Direct payback also fails as a substitute for causal evaluation. In one adopted path, direct net saving is \$11.21, but total B-minus-A outcome is \$ − 48.78. A pause, different allocation or pricing response can consume a component-level saving.

8.2 A concrete policy inadequacy

An independent reviewer inspected existing histories without changing or running new scenarios. In the low-friction, .5-arrival, ten-minute, deterministic adoption-earned slice, the original enterprise

posted $80 during 506 of 624 enterprise-weeks and won none of 2,167 offers at that price. It posted $20 for 18 weeks and won 17 of 87 offers. The margin-weighted optimism term can keep an unbought high price attractive in a finite market with few observations. The earlier failures therefore mix market conditions with a poor pricing heuristic.

This is a concrete reason for a final bounded policy diagnostic, publicly frozen before its outcomes [18]. It is not a reason to delete earlier outcomes or select an undisclosed favorable model. The diagnostic uses the unchanged core and all five already-declared fixed target prices, with the existing cost floor exposed. It evaluates 160 configurations: two integration costs, two arrival rates, ten assumed avoided minutes, both buyer rules and four funding/cost regimes, on the same twelve exploratory seeds. The matched draws enable policy comparison; they are not independent confirmation after selection. Every target, failure and actual posted-price range is retained.

8.3 A narrow prospective deployment region

The final diagnostic completes 1,920 paired worlds. B adopts in 398, all under the seed-inclusive funding policy: 199 full-history and 199 adoption-only. No earned-funded path adopts. Four of 160 conditions have positive mean B profit. Every one uses zero integration cost, .5 arrival probability and adoption-only seed funding: the $10/$20 targets under deterministic/logit choice. Their mean profits are respectively $129.51, $106.46, $96.72 and $183.28. No $10-integration or .25-arrival condition has positive mean B profit.

Twenty conditions have positive mean B-minus-A outcome, all adoption-only seed-funded; fifteen have a positive lower conditional Monte Carlo bound. Across individual worlds, 82 B paths are profitable: 66 adoption-only seed, 14 adoption-only earned with no adoption, and two full-history seed paths. The two individually profitable full-history paths still perform worse than their A counterparts. Across the diagnostic, 62 B worlds combine positive profit with positive incremental value, all adoption-only seed-inclusive. Seventy-two direct-payback worlds nevertheless have negative B-minus-A value. These counts do not estimate a real enterprise's success probability. No full-history condition has positive mean B profit or positive mean B-minus-A effect.

Table 3: Preselected diagnostic slice: $20 target, zero integration, .5 work arrival, ten assumed avoided minutes, logit, twelve reused seeds. A mean profit is $ − 1.69 in all rows. Monetary values are simulated USD.

Cost and funding basis	B mean profit	B–A mean	Adopted	Profitable
Full history; earned	−363.21	−361.52	0/12	0/12
Adoption only; earned	−1.69	0.00	0/12	4/12
Full history; seed	−178.24	−176.55	12/12	1/12
Adoption only; seed	183.28	184.97	12/12	12/12

Prospective B profit ranges from $15.03 to $397.09, with median $122.65 and sample standard deviation $119.69. Paired gains range $62.31–$314.62, median $158.36, standard deviation $78.06. With historical cost included, 11/12 B paths lose money: the range is $ − 346.49–$35.57, median $ − 238.87. Every paired investment effect is negative in that full-history condition, from $ − 299.21 to $ − 46.90. These are realized model dispersions, not uncertainty bounds on real markets.

In the last row the mean-profit interval is [$115.56, $251.00], and the paired increment interval is [$140.80, $229.13]. All twelve paths directly repay the prospective adoption and upkeep. The $20 quote remains $20 before and after adoption, so this slice does not depend on a hidden automatic price reduction. At the $10 target, actual quotes fall from the $14.33 cost floor to $10 after adoption; that channel is explicitly recorded.

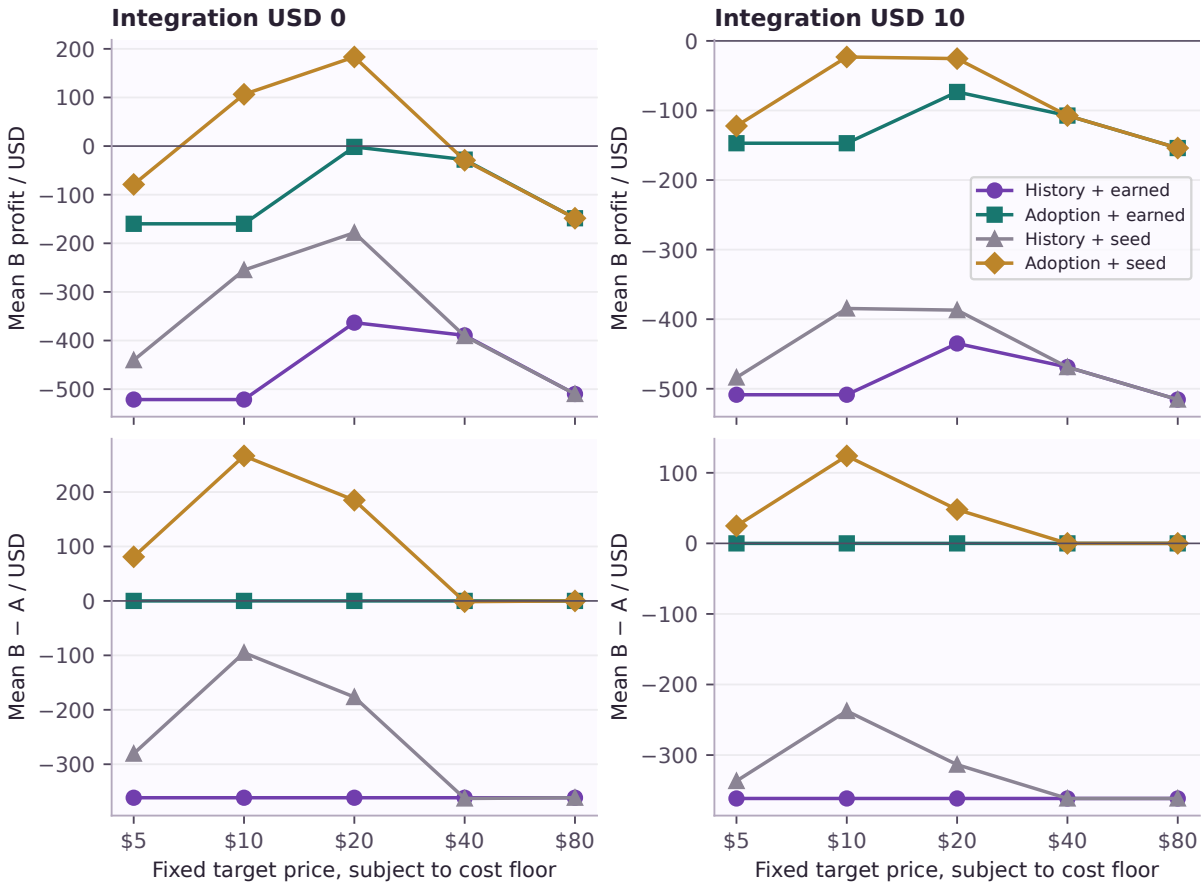

Figure 3: All five target policies in the predeclared figure slice, including losing prices. Top: mean B economic profit. Bottom: paired B-minus-A effect. Arrival .5, ten assumed avoided minutes and logit are fixed. Adding $10 integration eliminates positive mean profit. Full-history and prospective accounting are never pooled. Exact intervals and all 160 configurations appear in the companion table.

8.4 One connected enterprise history

The preselected seed 2001 illustrates deployment without selecting a winning trajectory after the run. Under adoption-only seed funding it has 282 new-work opportunities, of which 213 fit scope. The enterprise attempts 29, accepts 28 and rejects one; alternatives and deferral handle the rest. At week 8, $745.37 is currently available after obligations and reserve. The exact producer's $32.69 prospective adoption charge fits that cash, service pauses one week and the asset becomes available at week 9. It is used on 17 subsequent modeled jobs.

The same enterprise collects $560, incurs $437.35 total declared prospective costs including a $20 refund, and finishes with $122.65 profit and $1,122.65 cash. Adoption plus upkeep is $54.19; direct avoided cost is $190.75. Its paired incremental gain is $136.56. The AI competitor responds with lower quotes and pays $200 for its declared automation at week 12. All these events are simulated; the source-bound packet remains the actual production evidence.

The earned-surplus gate still reports $\$-77.35$, because this financing rule withholds a $200 reserve from accumulated net earnings as well as checking liquidity. Available cash and earned funding are deliberately different. The same path including historical research finishes at $\$-238.87$ profit and $\$-224.96$ incremental value. A visible cash balance therefore cannot be presented as historical cost repayment. Sixteen other diagnostic paths end with positive earned availability after the reserve, but none has a second constructed and tested asset to purchase.

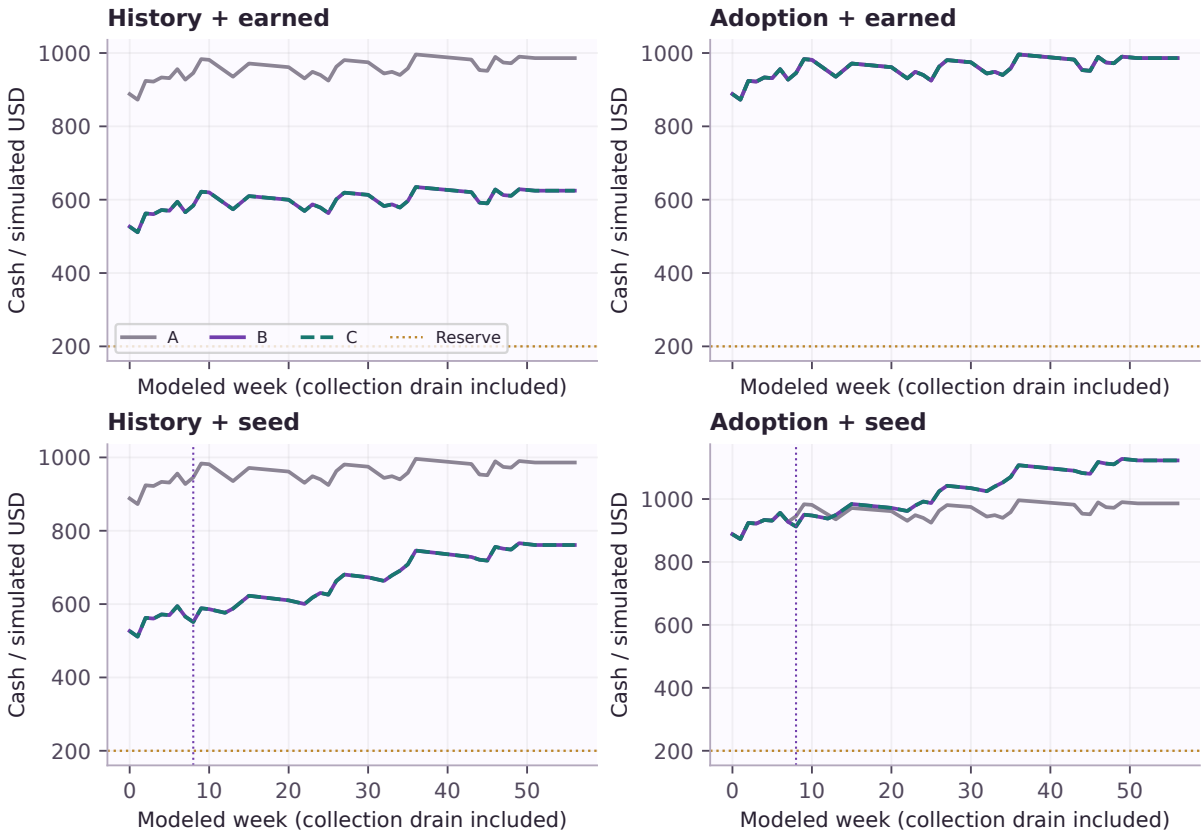

Figure 4: The same preselected seed across four accounting/funding regimes. B and C overlap. Dotted vertical lines mark adoption; the horizontal line is the liquidity reserve. Final collection weeks remain in the trace. No later hypothetical asset is purchased.

The narrow prospective region is a post-exploratory diagnostic on reused seeds. At this stage, it has not been independently confirmed or stress-validated under every fixed-price interaction. The earlier cheap-competitor, maintenance and quality stresses remain preserved, but their heuristic-price outcomes cannot certify robustness of these new target policies. A separately frozen fresh-seed extension follows below. It probes robustness of this selected policy without identifying an optimal price or outside-market predictive performance.

9 Viable regions, thresholds and what reverses the result

9.1 Demand has a ceiling as well as a supplier cost floor

Let $U_{it}^{*} = \max(0, \max_{j \neq E} U_{ijt})$ denote the buyer's best feasible alternative. A deterministic enterprise purchase requires a price below

$$p_{it}^{\max} = \hat{q}_{iEt} V_i - w_i e_{iEt} - (1 - \hat{q}_{iEt}) L_i - d_{iEt} - s_{iEt} - U_{it}^{*}, \tag{3}$$

subject to capacity and budget. Equality can tie under the specified rule. A retained capability can lower an affordable cost floor, while trust, usefulness, customer work and competitors determine this ceiling. There need not be a profitable interval between them.

One exact primary replay illustrates the identity. At week 1, buyer 0 has an enterprise ceiling of approximately \$10.47, while the reference policy posts \$40. In the zero-minute scenario the same buyer purchases a \$10 offer, with only about \$0.47 utility advantage. Another buyer's ceiling is approximately $\$ - 11.64$; even a free offer loses because the modeled remaining work, risk and

friction exceed the alternatives. These are conditional utility calculations, not elicited willingness to pay.

9.2 Repayment is path-dependent

For a realized paired path, define K_{charged} as the complete one-off capability expense actually incurred under the declared accounting basis. The fixed-path threshold

$$K_{\max}^{\text{path}} = \Delta_{BA} + K_{\text{charged}} \tag{4}$$

is the maximum one-off cost consistent with nonnegative incremental value *holding that realized path fixed*. Maintenance, competition and forgone delivery remain inside Δ_{BA}. This is an accounting diagnostic, not a global break-even theorem: changing cost can change adoption eligibility, timing, pricing, sales and solvency. Unknown real costs remain unknown.

For an even simpler necessary saving calculation, ten avoided minutes at the wage anchor equal about $10.90 per completed use before customer price pass-through, upkeep, failure and foregone work. A $361.52 historical bill would require more than 33 such fully retained savings even before those other charges. Zero measured human minutes would yield zero such labor saving. This illustrates the sensitivity; it does not assert that the action really takes ten minutes or that 34 buyers will appear.

9.3 Most consequential uncertainties

The result can reverse with the true finalization burden, full engineering/authoring cost, arrival rate, buyer integration work, trust, quality under real use, competitive task prices and pricing policy. Collection delay can make a positive-looking investment unaffordable. Maintenance or a failed integration can erase direct savings. Cheaper AI and competent human providers reduce the reservation-price ceiling. A free conventional workflow remains a credible option when the customer's remaining effort is small.

The experiments vary market environments and impose quality shocks, but the four fresh technical missions are related tuples of previously exposed libraries. They do not identify an independent distribution of field production difficulty. All Monte Carlo intervals describe randomness within one declared model; they exclude this larger model and parameter uncertainty. No market size, adoption curve or global profitable equilibrium is inferred.

10 Validation, demonstration and successive cycles

The independent same-session review exercised 26 controls against the final frozen core: cash reconstruction; binding budgets and reserves; accepted-only invoices; defaults and refunds; zero demand; dominated offers; free perfect DIY; common random draws; B/C symmetry; failed integration; and no investment or asset use before affordability/availability. Earlier failed controls and their correction receipts remain in the companion. Not every intermediate development source version was captured; those old failure logs are evidence of the development process, not a claim of exact replay of every superseded version.

All original studied-enterprise histories were independently re-audited, including every bill, invoice, cash event, investment and canonical projection. The reviewer is another agent in the same session, not an organizationally external auditor. The final diagnostic receives the same review. An output-only replay exposes all competitor invoices, bills and cash events without changing any original returned field in 6,480 paired worlds. Its independent audit covers 38,880 competitor accounts. The bounded continuation separately audits all 9,216 enterprise and 18,432 competitor

histories; the pure funding view has synthetic and independent controls. An offline browser check exercises the actual bilingual interface, downloads exact packet bytes, checks reference/control scenarios, verifies narrow layouts and rejects external network requests. The demo executes the same frozen simulation arithmetic.

The English/French laboratory lets readers inspect four actual packet downloads, quality evidence, CPU/wall records, unknown costs and source hashes, then change demand, review effort, integration, pricing, collections, funding and cost basis. A/B/C outcomes remain side by side. A connected history exposes buyer choices, competitors, invoices, collections, cash, obligations, adoption and subsequent asset uses. Measured and simulated panels use separate labels.

The study follows the same modeled enterprise over time, rather than splicing successful trajectories from unrelated firms. It does not demonstrate a second constructed productive asset. The selected cache candidate was not economically justified by the observed burden; the importer was an existing owner's work. Consequently, reserves can remain available without authorizing a fictitious successor. Basic conditional commercial viability, historical investment repayment, a second improvement cycle and self-acceleration remain distinct claims. Construction becoming more effective across comparable fresh problems has not been established.

11 Protocol, currency and authority boundaries

All four repositories were inspected and pinned. The AGI ALPHA production engine, inherited capability records, canonical ledger and existing publication coordination remain intact. The Fleet execution hold is respected. The corrected public importer snapshot is exported inertly; it creates no active proof, runtime authority or settlement.

The AGIJobs $\$AGIALPHA$ routes and the Manager's USDC6 route remain separate verified code paths. This model uses USD scenario units and invokes neither. It includes no token issuance, appreciation, gross-transfer profit, distribution, buyback or holder rights. There is no new credential, subscription, spending, customer outreach or deployed-contract change. Successful local arithmetic does not confer financial or operational authority.

12 From deployment value to financeable succession

12.1 A bounded continuation with fresh seeds

The user's continuation asks how far the narrow deployment result can extend. It does not replace any original experiment. Before fresh outcomes, we declared a 128-condition extension, 24 new seeds (3001–3024), the same 52-week horizon, $\$1,000$ initial capital and \$200 reserve, with no replenishment. The \$20 target is inherited from the identified diagnostic slice; this is an explicitly selected-policy exploratory extension, not a new primary test or a search over prices. Its complete freeze was publicly recorded before execution [20].

The main 48-cell grid crosses integration costs \$0/\$2.50/\$5/\$10, work arrival .1/.25/.5, deterministic/logit buyers and full-history/adoption-only accounting. Eighty adverse corners test weekly upkeep of \$2/\$5, collection delays of 6/13 weeks, cheaper AI, cheaper humans, undercutting, a quality shock, failed initial integration and dissatisfaction. Each intervention is specified at zero/\$5 integration, .5 arrival, both buyer rules and both cost bases. The failed-integration corner means immediate detection with a full charge and no forced downtime; it does not represent a prolonged failed installation. Other calibration and the core economic rules stay unchanged. No horizon extension or relaxation of buyer preferences is allowed after outcomes.

The research envelope limits the new market run to 120 wall and CPU seconds and sets an 18:10:33

UTC research cutoff. Discovery is capped at three burdens and fifteen minutes; at most one justified prototype could use twenty minutes of implementation and six fresh confirmation missions across three arms. Unfinished work must be labeled unfinished. Publication and custody work are separately recorded.

12.2 A source-of-funds view without invented money

Initial external funding does not itself disqualify a Flywheel. The question is whether later productive activity generates resources that can finance another worthwhile asset without repeated injections. Three accounts are therefore kept separate: prospective deployment, full historical return and funding provenance.

The original strict earned-funds policy remains unchanged. A second read-only attribution view deducts one reserve in the liquidity bound. Let H_t^{seed} be only a verified historical research bill paid from opening seed before any collections; U_t is an outstanding generated-resource earmark not already accrued as expense. Then

$$G_t = \max\Big[0,\, \min(C_t - O_t - R,\; Y_t - E_t + H_t^{\text{seed}}) - U_t\Big]. \tag{5}$$

Here Y_t is collected revenue and E_t all accrued expenses. Setup, first adoption, delivery, failed integration, upkeep and refunds remain inside E_t. Historical research stays charged once in cash and full-return profit; it is excluded only from the prospective operating-generation recovery subtotal. Unpaid or later research is never added back. An earmark reduces both the cash and generation bounds, and is released when its bill accrues. No actual second-asset commitment exists, so $U_t = 0$ in this study.

This convention identifies a funding ceiling, not an extra cash balance or a transfer. The adoption-only end-of-year seed-2001 example has \$122.65 in generated resources under Equation 5, while its original strict metric remains $\$ - 77.35$. Its \$200 liquidity reserve is protected in both views. A sensitivity also requires historical research recovery in the generation bound.

The new discovery itself has unknown authoring/inference and human monetary cost. Denote this incremental unpriced cost $D \geq 0$; it is not silently reclassified into the old historical bill or treated as zero. Before new decisions alter a path, available funds after that discovery are bounded above by $\max(0, G_t - D)$, and its economic return falls by its attributed D. For paired arms the fixed-path effect becomes $\Delta_{BA}^{\text{after}} = \Delta_{BA}^{\text{before}} - (D_B - D_A)$; unidentified differential discovery costs do not automatically cancel. Reported G_t is consequently *before this unpriced discovery*, not an all-in investment budget. The complete cost of any candidate would have to fit the remaining amount.

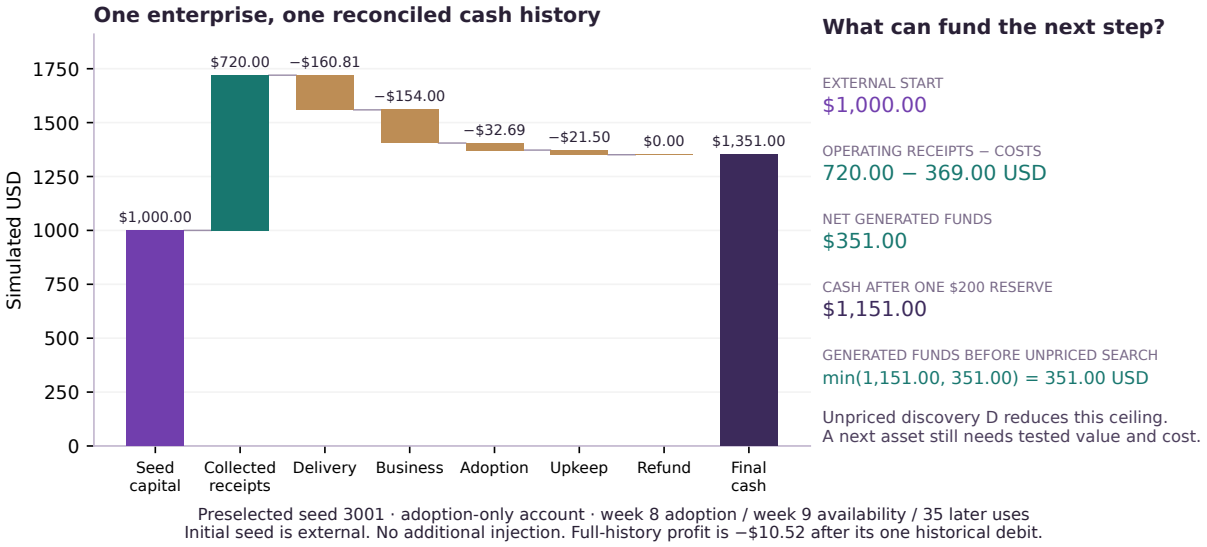

Figure 5: Starting capital, productive collections, costs, reserves and the exact retained investment in the connected fresh-seed path selected before extension outcomes. The provenance view exposes generated funds while preserving the historical-return loss. The funding ceiling precedes the unpriced new discovery cost D; no hypothetical successor is purchased.

12.3 Fresh-seed outcomes and the viable region

The registered extension completed all 3,072 paired worlds and 9,216 enterprise histories at 17:27:04 UTC, before the scientific cutoff. Its bounded invocation used 53.97 wall seconds and 60.52 child CPU seconds, below both 120-second limits. All 128 declared conditions are retained. Every monetary result in this subsection precedes the unpriced incremental discovery cost D. This qualification applies to profit, paired effects and funding ceilings.

At the predeclared reference—$20, zero integration, .5 arrival, logit choice and seed-inclusive prospective adoption—mean B profit is $151.70, with conditional 95% Monte Carlo interval [$93.56, $209.84]. The paired gain is $173.67, interval [$137.44, $209.90]. A's mean profit is $ − 21.97. All 24 B paths adopt, but three lose money. B profit ranges from $ − 140.33 to $474.62, median $148.67, sample standard deviation $145.32. Paired gains range from $0.31 to $338.21, median $169.26, standard deviation $90.55. Thus the fresh simulation retains a positive conditional mean deployment effect while exposing downside absent from the original twelve-world slice.

Charging the same $361.52 historical allowance once changes reference mean B profit to $ − 209.82 and its mean paired effect to $ − 187.85; every reference paired effect is then negative. Across all 64 full-history extension conditions, none has positive mean B profit or positive mean B-minus-A. There are nevertheless 22 individual full-history worlds with both a profit and a positive paired effect. These finite paths must not be erased, nor treated as an estimated real-world success probability. Across the 64 prospective conditions, 18 have positive mean B profit and 47 have positive mean B-minus-A. B and C tie exactly throughout.

Table 4: Fresh-seed main grid at .5 arrival. Prospective B profit and paired gain, before unpriced discovery; 24 worlds per row. Parentheses give conditional 95% Monte Carlo intervals. Integration cost is buyer friction, not supplier revenue.

Choice	Integration	Mean B profit (USD)	Mean B–A	Losses
Logit	0.00	151.70 (93.56, 209.84)	173.67	3/24
Logit	2.50	110.17 (54.48, 165.85)	147.42	5/24
Logit	5.00	65.30 (7.25, 123.36)	114.24	10/24
Logit	10.00	−23.69 (−69.02, 21.64)	59.71	16/24
Deterministic	0.00	61.39 (−54.65, 177.43)	107.26	13/24
Deterministic	2.50	−10.40 (−90.35, 69.55)	60.48	16/24
Deterministic	5.00	−57.83 (−111.96, −3.70)	47.25	18/24
Deterministic	10.00	−118.57 (−144.41, −92.74)	6.24	23/24

In the logit grid, mean prospective profit changes sign between $5 and $10 integration. The deterministic grid changes sign between $0 and $2.50, and even its zero-friction mean has a wide interval and a majority of losing paths. At .25 or .1 arrival, no main-grid condition has positive mean B profit. These are sampled sign brackets, not fitted exact break-even points, a universal monotonicity result or a license to extrapolate demand. The assumed ten provider minutes remain essential unidentified input; fresh market seeds do not turn an AI finalization-action count into measured human effort.

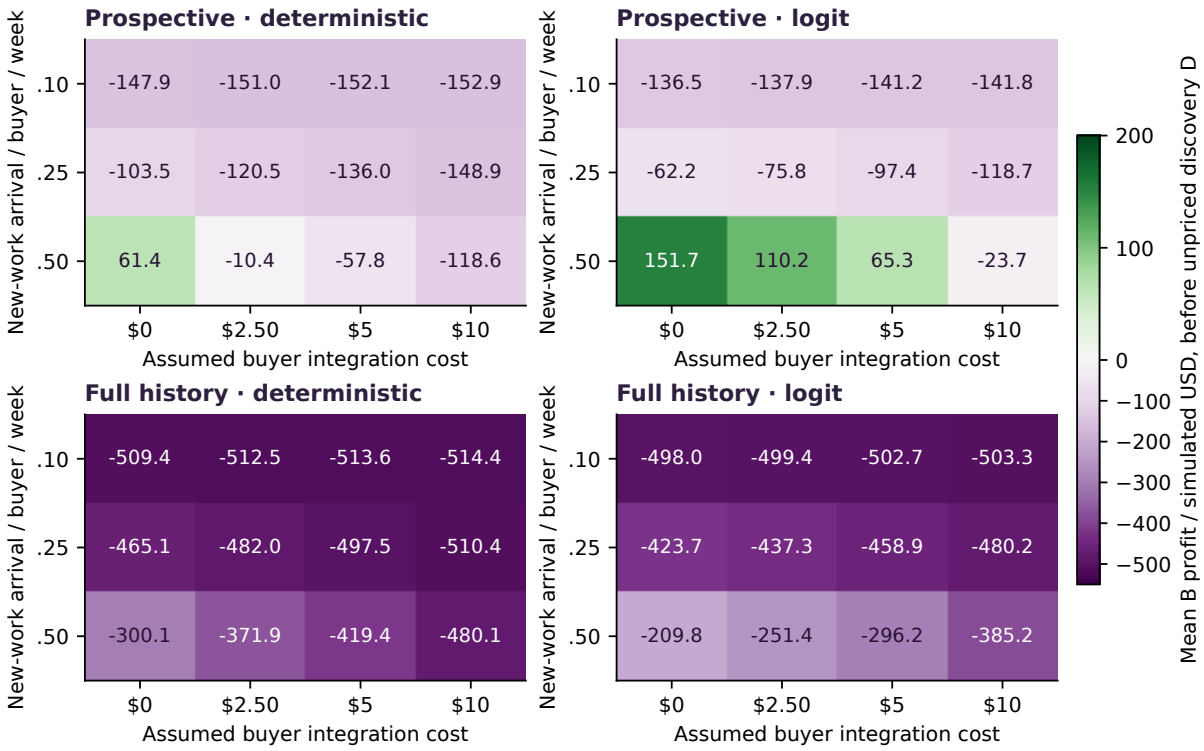

Figure 6: Every main extension cell, with the original horizon and capital. The prospective region is sensitive to integration, recurrence and buyer-choice specification. Full-history accounting remains separate. Values exclude the new unpriced discovery cost.

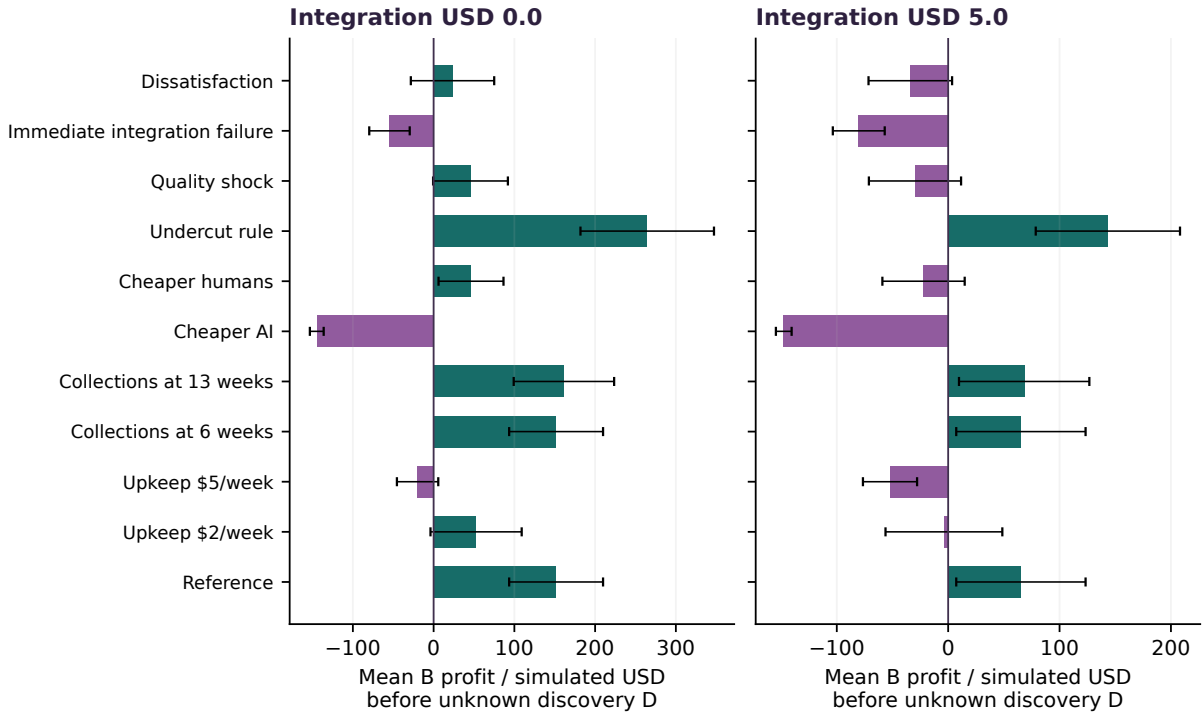

Figure 7: All ten predeclared perturbations and the reference for logit buyers at .5 arrival, prospective accounting and zero/$5 integration. Intervals describe Monte Carlo variation, not identified market parameters. A perturbation is not guaranteed to worsen outcomes under every behavioral response. The complete table retains both buyer rules and both cost bases.

At zero integration, $2 weekly upkeep lowers mean B profit to $52.60; $5 upkeep lowers it to $\$-19.85$. Cheaper AI removes deployment value: mean profit is $\$-144.71$ and mean B-minus-A is $\$-0.44$. Cheaper human provision gives $46.31 mean profit, the quality shock $45.66, and dissatisfaction $23.40; each becomes a negative mean at $5 integration. Immediately detected failed integration produces $\$-54.66$ profit and $\$-32.69$ incremental value at zero integration. It is a charged failure, not a free retry.

Collection timing alone does not necessarily reduce terminal profit when reserves cover the lag and contracted receipts are drained. Six weeks reproduces the reference mean; thirteen weeks gives $161.37. Existing-event inspection finds 21/96 first buyer-choice divergences across both integration levels and buyer rules; every one has unchanged quoted prices and a human-provider cash gate that passes in the reference but binds under the longer delay. For seed 3008 at week 35, a $67.50 delivery requirement fits $504.05 of reference human-provider cash but exceeds $60.35 in the delayed path; that buyer switches to the enterprise. No competitor insolvency occurs in these inspected cells. Despite higher terminal mean B profit, the reference mean maximum during-service funding ceiling falls from $153.04 to $69.68. Payment timing can constrain succession before final accounting catches up.

The undercut rule gives $264.54 mean profit because it sets the AI quote at $16, whereas the adaptive reference reaches $7–$17. Fully 1,217 of 1,248 recorded reference weekly quotes are below $16; mean accepted AI jobs fall from 48.54 to 26.71, and enterprise accepted jobs rise from 25.04 to 31.83. Undercutting the enterprise's $20 is therefore weaker competition than many reference markdowns. These declared interventions are not uniformly harsher conditions. The arithmetic inspection uses existing histories only; it establishes a mechanism within this behavioral model, not a general benefit of delayed payment, a favorable equilibrium or a real-world competitive advantage.

12.4 Generated resources exist, but do not establish a second cycle

The reference's mean terminal G is \$162.29, median \$148.67, range \$0–\$474.62. Twenty-one of 24 paths have a positive terminal ceiling; twenty have one during the productive year. This is a mean of nonnegative per-path ceilings, not the mean profit of \$151.70. Charging historical research once does not automatically erase operating generation: the cash bound still protects obligations and the reserve. The stricter original prospective metric has mean $\$ - 48.30$.

The registered representative seed 3001 connects the entire sequence without selecting a trajectory after outcomes. It has 321 changed-work opportunities, 249 supported, forty attempted deliveries, 37 accepted and three rejected. Initial adoption costs \$32.69 at week 8; the exact first asset becomes available at week 9 and serves 35 later modeled jobs. Gross invoices are \$740; \$720 is collected and \$20 defaults. There are no refunds. Declared prospective costs total \$369: \$154 business, \$160.81 delivery, \$32.69 adoption and \$21.50 upkeep. Profit is \$351, cash $\$1,351$, and the paired gain \$338.21. After the historical debit, profit is $\$ - 10.52$, cash \$989.48 and paired gain $\$ - 23.31$. The historical loss is visible even though the prospective operating-generation ceiling is \$351 under both cost bases.

This path first has a positive G at week 19; its maximum during the productive year is \$311, followed by \$351 after collections drain. The original strict metrics are \$151 prospective and $\$ - 210.52$ full-history. These amounts cannot be spent before they exist. No second asset is bought at any date.

For this path, a future investment could fit at most $\max(0, 351 - D)$ dollars after the new discovery, subject to its own timing, obligations and qualification. For the reference mean, an attributed expected D_B reduces \$151.70 of prospective profit dollar for dollar; the paired benefit is also reduced by the differential cost $D_B - D_A$. Neither cost is identified. Accordingly, the study establishes a conditional supply of generated resources, not all-in affordability or repayment of an unbuilt successor.

12.5 The second-capability gate: no qualified purchase

The bounded discovery examined three burdens in 321.8 elapsed seconds, not measured human labor. Broader native application qualification is the most promising service direction: it could extend a maintainer's component evidence into a fuller release decision. However, the current 61-case closure does not identify an authorized, reproducible broader contract, measured remaining effort, complete cost bounds or a prospectively frozen fresh cohort.

Additional environment reuse already benefits all arms. The entire five-environment setup costs 19.894 CPU seconds, and changed tuples still require validation. No material extra attention benefit is measured. Publication and accounting custody repairs are necessary research work, but do not provide another productive capability for this component-assessment buyer. The previously rejected baseline cache and existing importer owner's boundary remain intact.

The gate is therefore **NO-GO before construction**. There is no second implementation, fresh second-asset confirmation, purchase, new customer job or claimed second-asset saving. This does not say all future assets are worthless, and it does not erase the existing B/C deployment value. The missing condition is a source-identified, worthwhile and tested next asset whose complete cost fits generated funds after discovery, obligations and reserves. Positive cash availability alone cannot supply that evidence.

12.6 An evidence ladder

Table 5: Claims advance only as far as their evidence. Economic thresholds remain conditional on declared scenarios and unidentified costs.

Rung	Supported status
Executed useful production	Established in the finite component scope: four fresh joint questions, twelve complete assessments, actual reviewable decision packets.
Conditional deployment value	Positive within specified model conditions; preserved primary failures and adverse outcomes remain visible. Original and fresh-seed results are separately labeled.
Full investment repayment	No tested full-history configuration has positive mean profit or investment effect. Some individual paths do; actual all-in cost remains unknown.
Generated financing of a subsequent tested asset	Funding ceilings can be computed, but no qualified second capability exists and its discovery cost is unpriced. A second cycle is not established.
Actual market receipts	Zero observed collections; no actual adoption is inferred from simulated buyers or invoices.
Superior improvement process or self-acceleration	Not established. Conventional C ties B; construction efficiency on comparable fresh problems has not been demonstrated.

13 Conclusion

The executed contribution is four new grouped dependency questions, twelve accepted finite-scope assessments, exact replayable decision packets and a retained evidence-bound producer tested on fresh tuples. Its automated finalization is real. A conventional builder matches its accepted quality; human labor saved, all-in construction money and field reliability are not measured.

External evidence supplies labor anchors, practical conventional and AI alternatives, real maintenance obligations and heterogeneous attitudes. Prices for this exact packet, recurring purchase frequency, task value, human durations, integration effort and payment behavior remain assumptions. All financial trajectories are simulations, and observed customer collections are zero.

The frozen primary result is negative. A later, explicitly exploratory pricing diagnostic finds conditional value from deploying the existing asset. At the preselected \$20 target, zero integration, higher assumed recurrence and logit choice, mean prospective B profit is \$183.28 and mean B-minus-A is \$184.97 across twelve worlds. Including the declared historical cost gives $\$ - 178.24$ mean B profit; eleven worlds lose money. Those results remain unchanged.

The separately registered continuation tests that policy in 24 fresh worlds per condition. At the same reference, prospective profit averages \$151.70, with three losing worlds, and the paired gain averages \$173.67, before the new unpriced discovery cost. Positive mean profit survives \$2.50 and \$5 integration under logit choice; it fails at \$10, at the lower recurrence levels, and against the specified cheaper AI. Deterministic buyers make the result less favorable. Upkeep, human competition, quality shocks and dissatisfaction further constrain it. No tested full-history configuration in any campaign has positive mean B profit or positive mean B-minus-A. This is not universal nonviability: the extension includes 22 individual full-history worlds with both quantities positive.

Prospective deployment, full repayment and succession therefore have different answers. The actual existing asset can be worth adopting from the current decision point. Full historical repayment is not established. Some enterprises also generate resources that could contribute to later investment without replenishing seed capital. In the preselected fresh path, \$720 of collections minus \$369 of prospective costs leaves \$351; obligations and a \$200 reserve fit within cash. The historical debit remains visible, leaving full-history profit of $\$ - 10.52$. The new discovery cost D is unpriced, so \$351 is a ceiling before D, not an all-in spendable commitment.

No second capability passed the bounded qualification gate. Broader native qualification needs a defined contract and fresh evidence; additional environment reuse lacks a measured material burden; research custody repairs are not another buyer-facing production asset. The missing condition is a distinct tested improvement whose complete cost fits actual then-available generated funds and whose incremental benefits justify that cost. The experiment ends with no second construction or purchase. It does not infer a second cycle from a balance, a scheduler or a diagram.

The most consequential uncertainties are competent-human finalization time, complete historical and prospective engineering cost, buyer integration and review effort, recurring purchase frequency, choice behavior and competing offers. The conventional tie does not erase useful service or asset value; it limits the claim of a distinctive construction-method advantage. Actual customer adoption, collected market revenue, earned financing of a subsequent tested capability, self-acceleration and real-world self-financing remain unestablished.

A Evidence inventory and custody

Record	Identity and interpretation
Fresh production freeze	`2da7e8191eb2fb80adcd7d808d0494ab3247313e997607e7166e71c352ea7cee`. 144 exact source/input files; public before outcome.
Fresh campaign	`80ead6855a65d56dc2de4c84dc2063eefef92ae0d4c84421dfcd372b852f8084`. Four missions, twelve assessments; zero actual customer collections.
Retained asset B	`0b4eb1ae2392176ff61ef91b7da0d13df3c6400ee0b3e317439238881adc182d`. Exact source financed in every applicable model history.
Conventional asset C	`cd28579ecf72eba5bdfffa6b3b5483aaaa960322989d2a2369da5431062207ba`. Strong reusable builder; its receipt checker is adopted by B.
Final market core	`52b7d83b57de1ca1cf43e444cedb3639193c91b2d6816f3ba86f9463dd904f27`. Shared unchanged across all four campaigns and the demo.
Primary freeze	`7bbb0919ede3d4389d9eb36c23a7b775ec8093e40d51ac4da3f9c5714920406d`. 87 configurations; seeds 1001–1024.
Exploratory freeze	`7b4eb9450278cbe00400f442d964191a4bf15fd6726966955c03a0ebd22fa875`. 206 configurations; seeds 2001–2012.
Pricing diagnostic freeze	`640492e70fa9c4af9cd7093da24248b7b141cedb770941033a36e91f9094ea55`. 160 configurations; reused seeds 2001–2012.
Bounded continuation freeze	`e822d8a49f1d13f117543e17f628a8e230e672bc7d15b4d1bed4f5383f5bfd55`. 128 configurations; fresh seeds 3001–3024.
Funding provenance module	`7c017e77f26ca7c755e8fb832ec4e7eddfe241c758b769931e72fadedbb3e083`. Read-only source-of-funds ceiling; discovery cost remains unknown.
Production closure	`031ac7a8098fc57267c552dda68963680291b3635a9132a4c9030025d04beb39`. Manifest binds 1,498 selected files, 82,321,090 raw bytes.
Relocated production replay	`20bcd214f037b8e5884f34c407fe02de27a02f28aaa4d3cf40350e1801e619c0`. Exact semantic agreement; zero additional unique missions.

The inherited six-transition campaign, prior publications and failed custom candidate remain distinct. Historical economic records are preserved with their disclosed custody gap; a missing old upload receipt is not reconstructed as an observed original. The corrected importer is pinned at commit `269af6f9dd8d511fc387d0cecdff62a88ea96b02`; later owner edits are not silently incorporated. The offline companion contains wheel licenses and source notices.

B Selected parameter and uncertainty ledger

Quantity	Declared value or range	Identification / consequence
Field quality	Enterprise .95; human .97; DIY .95; AI .90	Scenario values, not inferred from 4/4 or 6/6. Shocks and feedback affect choice and refunds.
New-work arrival	.25/week reference; 0/.1/.5 alternatives	Assumed per-project process. Recurring obligations establish a need class, not this frequency.
Supported share	.75 reference	Scope-transport assumption. Unsupported work cannot create delivery revenue.
Provider finalization	0/2/10/30 minutes	Unknown human duration. The measured evidence is an explicit AI action count.

Quantity	Declared value or range	Identification / consequence
Customer effort	8 minutes enterprise; 6 human; 15 AI	Assumed; unchanged by retained-asset admission. DIY uses .65 of task effort.
Capital and reserve	$1,000; $200	Equal starting resources across arms. Not observed funding or earned profit.
Historical construction	.5/4/16/40 hours plus $100	Assumed whole-history allowance; no finite measured upper bound. Opening charge cannot be funded retroactively.
Prospective adoption	.5/4/16/40 hours	Existing solution may be adopted. Service pauses at least one week. No original R&D repayment in adoption-only rows.
Maintenance	$0.50/week reference; adverse variants	Scenario upkeep cost, charged only when relevant.
Collection	2-week delay, .98 payment probability	Assumed; 13-week stress and defaults expose liquidity risk.
Mechanical requirement	16.7994 wall / 2.5392 CPU seconds	Largest observed arm mean used as one-mission budget. Weekly machine availability remains assumed.
Service capacity	4 enterprise jobs / 120 attention minutes per week	Scenario bottleneck, not a demonstrated deployment-scale benchmark.
Review and trust	Initial prior .90; skeptical share .25	Behavioral assumptions; survey evidence does not identify these weights.
Pricing	Five targets, empirical or fixed-floor rules	Chosen strategy affects demand. Exhaustive target diagnostics are not optimized-policy confirmation.

The machine-readable parameter manifest covers additional timing, budgets, correction, refund, churn, competitor, forecasting and allocation variables. Full configuration snapshots are embedded in every paired history, so published results never depend on an undocumented default after the fact.

C Resource account and reproducible execution

Actual phase receipts distinguish local CPU, wall time, input hashes, exit status and unknown inference, authoring and human cost. Development failures, environment setup, verification, packaging and recovery are retained. The canonical resource meter's inclusive process-child CPU is used for phase accounting; nested task diagnostics are not summed again. No all-in monetary profitability claim is possible from these receipts alone.

The primary simulator campaign took about 20.83 wall seconds and 23.29 inclusive CPU seconds; the exploratory campaign about 30.24 and 33.37. These are local computational observations, not cloud bills or authoring costs. The diagnostic uses 24.67 wall and 27.25 CPU seconds. The continuation bounded invocation uses 53.97 wall and 60.52 CPU seconds. Exact receipts are included with each output. The 150.73-wall/155.62-CPU-second competitor export is separately classified as same-world custody replay, not a new economic campaign or a continuation research-budget charge. Software environment: Python 3.12 Linux x86_64 for frozen offline wheels, Node

24.22.1 for this local research run. This is not a claim of the repository's separate Node 22.17.1 release gate.

From the complete companion root:

```
# Validate the immutable production and financial records.
python3 production/audit_joint_results.py
node market/tests/test_market.mjs
node review/audit.mjs
node market/deployment-robustness/test-funding.mjs
python3 review/audit_outcomes.py market/results/primary-01 /tmp/primary-audit.json
# Repeat with exploratory or policy-diagnostic results and matching flags.
# See README for all exact commands; never overwrite a prior receipt.

# Frozen market runners reject an existing output directory.
node market/src/run.mjs --output /tmp/alpha-primary-replay
node market/exploratory/run.mjs --output /tmp/alpha-exploratory-replay
node market/policy-diagnostic/run.mjs --output /tmp/alpha-pricing-replay
node market/deployment-robustness/run.mjs --replay-registered --output /tmp/alpha-succession-replay

# Build the offline interface and publication.
python3 publication/build_demo.py
python3 publication/build_figures.py
python3 publication/build_succession_figures.py
python3 publication/build_finance_figure.py
cd publication
pdflatex -interaction=nonstopmode -halt-on-error paper.tex
pdflatex -interaction=nonstopmode -halt-on-error paper.tex
```

The continuation replay requires the original completed archive, verifies all fixed identities, and reproduces the same registered worlds after the research cutoff; it creates no new evidence. The root README supplies exact production instantiate/prepare/advance commands and path relocation rules. Use fresh outputs. Embedded historical absolute paths are custody records, not instructions to alter original locations. A full ZIP central-directory test, extraction and per-file manifest comparison checks delivery closure. The bounded repository source PR omits large histories/wheels and is clearly labeled; the complete companion provides them.

D Interpretive safeguards

A larger positive outcome in an interactive user-selected scenario is a conditional illustration. The reader has changed assumptions; it is not another independent market validation. Normal-approximation intervals across twelve or twenty-four seeds summarize Monte Carlo variability only. Closely related technical tuples, common scenario seeds and exhaustive grids do not supply independent real-world replications. Multiple prices are all disclosed; a best observed target is not described as a learned optimal strategy.

The product is deliberately scoped. It cannot certify all behavior, authentication, persistence, security, platform compatibility or release readiness. A verification helper's passing tests are not new buyer jobs. A positive supplier margin is not customer savings, and customer savings are not supplier profit. A source-bound HOLD is not an execution authorization.
